The Structured Coalescent

Ian Roberts

Homochronous Leaves

- Homochronous leaves occur when each lineage is sampled at the same time
- Each pair of lineages coalesces at constant rate 1, resulting in a combined coalescence rate of $\frac{1}{\theta}\binom{n_t}{2}$ where n_t denotes the number of lineages remaining in the sample at time t backwards in time and θ denotes the product of effective population and mutation rate
- Homochronous.Sim simulates the ordinary Kingman n-coalescent (Kingman 1982) with simultaneously sampled lineages
- Homochronous.Sim outputs a phylo object from the ape package (containing edge matrix, vector of edge lengths)

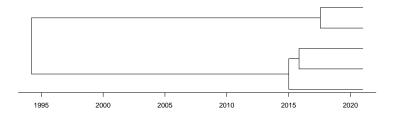

Figure 1: Homochronous *n*-coalescent simulation using Homochronous.Sim where Effective population \times generation length = 25

Heterochronous Leaves

- Heterochronous leaves occur when lineages are sampled at various times
- Heterochronous.sim again simulates the Kingman *n*-coalescent with lineages sampled at various times. Requires an additional input of the time of the sample measured in continuous years
- Reduces to Homochronous.sim if all leaves have the same age (homochronous leaves)

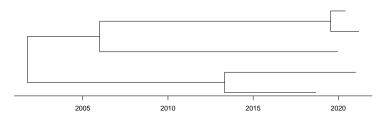

Figure 2: Heterochronous n-coalescent simulation using Homochronous.Sim where Effective population \times generation length = 25

Under the structured coalescent multiple populations or demes evolve with migration events occuring between distinct demes

- Each pair of lineages coalesce at rate 1, with an instantaneous coalescence rate $\frac{1}{\theta_i}\binom{n_{it}}{2}$, where n_{it} denotes the number of lineages in deme i at time t and θ_i denotes the product of the effective population size of deme i and mutation rate. Further, each lineage may migrate from deme i to deme j ($j \neq i$) at rate λ_{ii}
- Structured.sim generates a realisation of this structured coalescent process where at each event time, either:
 - Two lineages in the same deme coalesce
 - One lineage migrates between two demes

Example Simulation

- Augment the previous example dataset with an initial deme for each lineage
- ullet Assume 2 demes and an example migration matrix Λ

ID	Age	Deme
1	2021.014	1
2	2020.411	1
3	2021.200	2
4	2018.687	2
5	2019.958	2

$$\Lambda = \begin{bmatrix} 0 & 0.02 \\ 0.05 & 0 \end{bmatrix}$$

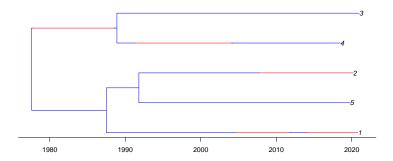

Figure 3: Structured heterochronous *n*-coalescent realisation using Structured.sim with Effective population \times generation length = 25 and migration rates 0.02 (1 \rightarrow 2) and 0.05 (2 \rightarrow 1)

Simulations obtained from Heterochronous.sim were verified via calculation of the log-likelihood

- The log-likelihood can be calculated recursively by considering the contributions made when either a new leaf is added, or a coalescence occurs
- This log-likelihood can be compared to the likelihood from Drummond et al. (2002),

$$L = \frac{1}{\theta^{n-1}} \prod_{i=2}^{2n-1} \exp\left\{-\frac{k_i(k_i-1)}{2\theta}(t_i-t_{i-1})\right\}$$

where

- t_i denotes the time of the ith event (either a coalescence or adding a newly sampled lineage)
- k_i denotes the number of current lineages at t_i
- \bullet denotes the product of effective population and generation length.

Simulations from Structured.Sim were verified via calculation of the log-likelihood with the exact form of the likelihood from Ewing, Nicholls, and Rodrigo (2004),

$$L = \prod_{i=1}^{d} \prod_{j \neq i}^{2n+M-1} \frac{1}{\theta_{i}^{c_{i}}} \lambda_{ij}^{m_{ij}} \exp \left\{ -\left(\frac{k_{ir}(k_{ir}-1)}{2\theta_{i}} + k_{ir}\lambda_{ij}\right)(t_{r} - t_{r-1}) \right\}$$

- where
 - n denotes the number of leaves
 - d denotes the number of demes
 - m gives a $d \times d$ matrix with entries m_{ii} giving the number of migrations $(i \rightarrow j)$ and $M = \sum_{i,i=1}^d m_{ij}$ gives the total number of migration events
 - c gives a d-dimensional vector with entries c_i giving the number of coalescence events occuring in deme i
 - k_{ir} denotes the number of lineages in deme i at time t_r

Recursive log-likelihood

The recursive log-likelihood for the structured coalescent can be calculated by summing the contributions when each node is added to the phylo. Nodes can be added in one of three ways:

- A new leaf is added
- A coalescence occurs in deme i
- A migration occurs $i \rightarrow j$

Likelihood contributions

Total coalescence rate $\mathcal{C} = \sum_{i=1}^d \frac{1}{\theta_i} \binom{k_i}{2}$, Total migration rate

$$\mathcal{M} = \sum_{i=1}^{d} \sum_{i \neq i} k_i \lambda_{ij}$$
 and Total event rate: $\mathcal{E} = \mathcal{C} + \mathcal{M}$.

- New leaf added:
 - $L \leftarrow L + \log (1 \mathcal{E} \exp\{-\mathcal{E} \delta\})$ where δ is the time to next new leaf being added
- Coalescence event in deme i:

$$L \leftarrow L + \log(\mathbb{P}[\mathsf{Coal}]\mathbb{P}[\mathsf{Coal} \ \mathsf{deme}]\mathbb{P}[\mathsf{Coal} \ \mathsf{pair}]f_{\mathcal{T}}(t))$$

$$= L + \log \left(\frac{\mathcal{C}}{\mathcal{E}} \cdot \frac{\frac{1}{\theta_i} \binom{k_i}{2}}{\sum_{j=1}^d \frac{1}{\theta_i} \binom{k_j}{2}} \cdot \binom{k_j}{2}^{-1} \cdot \mathcal{E} \exp\{-\mathcal{E}t\} \right) = L - \mathcal{E}t - \log \theta_i$$

• Migration event $i \rightarrow j$:

$$L \leftarrow L + \log(\mathbb{P}[Mig]\mathbb{P}[Mig \text{ origin}]\mathbb{P}[Mig \text{ target}]\mathbb{P}[Mig \text{ lineage}]f_T(t))$$

$$= L + \log \left(\frac{\mathcal{M}}{\mathcal{E}} \cdot \frac{k_i \sum_{\eta \neq i} \lambda_{i\eta}}{\sum_{\alpha = 1}^{d} k_{\alpha} \sum_{\beta \neq \alpha} \lambda_{\alpha\beta}} \cdot \frac{\lambda_{ij}}{\sum_{\gamma \neq i} \lambda_{i\gamma}} \cdot \frac{1}{k_i} \cdot \mathcal{E} \exp\{-\mathcal{E}t\} \right) = L - \mathcal{E}t + \log(\lambda_{ij})$$

Running 100 generated processes for the example dataset and comparing the exact likelihood (Ewing, Nicholls, and Rodrigo 2004) to the recursive likelihood. Maximum discrepancy over the 100 iterations was $1.2434498 \times 10^{-14}$.

```
N \leftarrow 100; likelihoods \leftarrow matrix(0, nrow = N, ncol = 2)
for (i in 1:N){
  phylo <- Structured.sim(struc.data, 1,1,2,migration.mat,1
  likelihoods[i,1] <- phylo$log.likelihood
  likelihoods[i,2] <- structured.likelihood(phylo,1,1,migra</pre>
max(abs(likelihoods[,2] - likelihoods[,1]))
```

Currently implementing a reversible-jump MCMC scheme to infer the migration events and migration rates for a fixed genealogy. Based on the work of:

- Drummond et al. (2002) who propose a reversible-jump MCMC scheme to simultaneously estimate the genealogy alongside the mutation rate and effective population size for a heterochronous coalescent model
- Ewing, Nicholls, and Rodrigo (2004) who develop this MCMC scheme to again simultaneously estimate the genealogy alongside the mutation rate, population size and migration rates for a structured coalescent model

Reversible Jump Moves

The selected reversible jump moves are those of Ewing, Nicholls, and Rodrigo (2004) which do not modify the (fixed) genealogy:

- Migration Birth/Death
- Migration Pair Birth/Death
- Coalescent Node Merge/Split

A migration birth/death move samples an ancestral node, r, uniformly at random and selects either a birth or death event with probability $\frac{1}{2}$,

- Birth event: Add one new migration node uniformly along the edge connecting r and parent(r), reselecting demes over the maximal connected subtree containing the edge $\langle r, parent(r) \rangle$ containing no interior migration nodes
- Death event: If the parent(r) is a migration node, delete parent(r) and reselect demes over the maximal connect subtree containing the edge $\langle r, parent^2(r) \rangle$ containing no interior migration nodes
- IMAGE OF MIGRATION BIRTH/DEATH???

Migration Pair Birth/Death

A migration pair birth/death move samples an edge, e, uniformly at random and selects either a birth or death event with probability $\frac{1}{2}$,

- Pair birth event: A pair of migration nodes are each added uniformly along e, selecting a deme different to the deme of e
- Pair death event: If both terminal nodes of e are migration nodes and lie in the same deme, both nodes are deleted and the deme between them is updated

Coalescent Node Merge/Split

A coalescent node merge/split samples a coalescent node, c, uniformly at random and selects either a merge or split event with probability $\frac{1}{2}$,

- Merge event: If both children of c are migration nodes lying in the same deme, the two migration nodes are pulled through c and merged onto the parent edge of c
- Split event: If parent(c) is a migration node, the migration node is pulled through c and split onto both child edges
